Gasoline Upgrading: Reforming, Isomerization, & Alkylation
Chapters 10 & 11
Gasoline Upgrading

Purpose
- Increase the quality of feed stocks of the same boiling range as gasoline

Characteristics
- Catalytic Reforming
  - Converts naphthenes to aromatics
  - Produces hydrogen
- Isomerization
  - Re-arranges straight chains to branched isomers
  - Very little change in boiling points
- Alkylation
  - Use olefins produced in other processes (primarily FCCU)
  - Produce isoctane
  - Liquid acid catalyst

Products
- Gasoline blend stocks of improved octane and/or volatility

Naphtha Reforming

Almost every refinery in the world has a reformer

Purpose to enhance aromatic content of naphtha
- Feed stocks to aromatics complex
- Improve the octane rating for gasoline

Many different commercial catalytic reforming processes
- Hydroforming
- Platforming
- Powerforming
- Ultraforming
- Thermofor catalytic reforming

Primary reactions
- Dehydrogenation
  - naphthenes → aromatics
- Isomerization
  - normal paraffins → branched isoparaffins
- Hydrogen as by-product
  - Ultimately used in hydrotreating
  - Catalytic reforming 2nd to FCC in commercial importance to refiners

Reformate desirable component for gasoline
- High octane number, low vapor pressure, very low sulfur levels, & low olefins concentration
- US regulations on levels of benzene, aromatics,
  & olefins
  - Air quality concerns
U.S. Refinery Implementation

EIA, Jan. 1, 2017 database, published June 2017

Characteristics of Petroleum Products

Reforming: drive off hydrogen for better gasoline properties w/o changing size
Feedstocks & Products

Hydrotreated heavy naphtha feedstock

- Light straight run naphtha tends to crack to butanes & lighter
- Gas oil streams tend to hydrocrack & deposit coke on the reforming catalyst

Catalyst is noble metal (e.g. platinum) – very sensitive to sulfur & nitrogen

- Feed stocks hydrotreated for sulfur & nitrogen removal
- Control of chloride & water also important

Severity

- High severity used to maximize aromatics
  - Sent to BTX separation for aromatic feedstocks
- Low severity used for gasoline blend stocks

Produces the majority of the hydrogen used for hydrotreating
Reforming Chemistry

Uses a solid catalyst to convert naphthenes to the corresponding aromatics & isomerize paraffinic structures to isomeric forms

- Both reactions lead to a marked increase in octane number
- Both reactions lead to volume shrinkage

Correlations permit the use of a PONA analysis of the feed for prediction of yield and quality of the product

- Originally feed qualities measured in terms of Watson "K" Factor — a rough indication of amount of paraffins

Aromatics largely untouched by reactions

Boiling Point Ranges for Products

Based on example problem in:
Gerald Kaes, Athens Printing Company, 02004
Effects of Process Variables

Primary control for changing conditions or qualities is reactor temperature

- Normally about 950°F at reactor inlet
- May be raised for declining catalyst activity or to compensate for lower quality feedstock
- Higher reactor temperature increases octane rating but reduces yield & run length

Design considerations for improvement in quality will include pressure, recycle ratio, reactor residence time, & catalyst activity

- Low reactor pressure increases yield & octane but increases coke make
- Increased hydrogen partial pressure due to hydrogen recycle (hydrogen to hydrocarbon ratio) suppresses coke formation, hydrogen yield & octane gain, but promotes hydrocracking
- Low space velocity favors aromatics formation but also promotes cracking by operating closer to equilibrium conditions
- Higher activity catalysts cost more but increases run lengths and/or yields
Specific Catalytic Reforming Processes

Hydroforming
- Early cyclic process used to produce toluene for TNT during World War II
- Molybdenum oxide on alumina catalyst
- Rapid coking of the catalyst, requiring a cyclic regeneration of reactors about every four hours
  - Timing mechanism used for lawn sprinkler systems used to switch from reforming to regeneration service
  - Reactor system included one extra "swing" reactor
    - Facilitate periodic removal & regeneration of a reactor

UOP Semi-Regenerative Platforming
- Low platinum
- Regeneration once a year
- Made naphtha octane improvement accessible to all refiners

UOP Continuous Regeneration of Reforming Catalyst
- Moving bed process
  - Continuously regenerating a portion of a moving bed of catalyst to remove coke & sustain activity
  - Operating pressures lowered to 50 psig
- Three reactors stacked one on top of the other
  - Gravity flow of the catalyst from top to bottom
  - Reactants pass radially through the catalyst to the inner conduit and then to the next bed
  - Mode of regeneration is proprietary – probably employs air or oxygen burning of the coke followed by reduction & acidification
UOP’s CCR Platforming™ Process

C4 & C5/C6 Isomerization

C₄ isomerization
- Convert nC₄ to iC₄
- iC₄ more desirable as alkylation feedstock

C₅/C₆ Isomerization
- Improve the octane rating of straight run gasoline
  - N-paraffins isomerized to branched isoparaffins
  - Will also convert any nC₄ to iC₄
- High RVP (about 17 psi) — limits its use in gasoline pool
U.S. Refinery Implementation

Updated: July 5, 2017

Characteristics of Petroleum Products

Isomerization: rearrange molecules for better gasoline properties w/o changing size
History of Isomerization

Aviation gasoline for World War II
- Butane isomerization was developed to create the needed isobutane feedstock
- Aluminum chloride catalyst
- Many of these units were shut down after the war

Tetra Ethyl Lead Phase-Out in 1970s
- Straight Run Gasoline (SRG) relied on TEL for octane improvement
- Research Octane Number (RON) of only 70
  - SRG mostly paraffinic pentanes & hexanes with some heptanes and octanes

Isomerization could provide needed octane boost
- Equivalent Isoparaffins have higher RON
C5/C6 Isomerization Processes

Vapor phase process

- Hydrogen used to suppress dehydrogenation & coking
- High yields & high selectivity to high-octane isomeric forms
- Provides moderate (but important) contribution to the gasoline pool

Catalyst types

- Chloride alumina catalyst
  - Organic chloride deposited on active metal sites
    - High temperature treatment with CCl4
  - Chlorides sensitive to moisture – drying of feed & hydrogen make-up essential
- Acidic zeolite with noble metal catalyst
  - Platinum catalyst
  - Does not require activation by HCl

Pros

- Reforming conditions not appropriate for the paraffinic components in SRG
- Essentially zero benzene, aromatics, & olefins
- Very low sulfur levels

Cons

- High vapor pressure
- Moderate octane levels — (R+M)/2 only 85
C5/C6 Isomerization – Feedstocks & Products

Lightest naphtha feed stock (SRG) with pentanes, hexanes, & small amounts of heptanes
  - Feed often debutanized — ‘Debutanized Straight Run’

Sulfur & nitrogen must be removed since catalysts employ an ‘acid site’ for activity
  - Merox
  - Clay treating
  - Hydrotreating

Common for Straight Run Gasoline & Naphtha to be hydrotreated as one stream & then separated

Products
  - Isoparaffins & cycloparaffins
  - Small amounts of light gasses from hydrocracking
  - Unconverted feedstock

Increased severity increases octane but also increases yield of light ends

Yields depend on feedstock characteristics & product octane
  - Poor quality feeds might yield 85% or less liquid product
  - Good feeds might yield 97% liquid product
Isomerization Chemistry

Primary reaction is to convert normal paraffins to isomeric paraffins

Olefins may isomerize and shift the position of the double bond
  - 1-butene could shift to a mixture of cis-2-butene & trans-2-butene

Cycloparaffins (naphthenes) may isomerize & break the ring forming an olefin
  - Cyclobutane to butene
Effects of Process Variables

Low temperature, moderate hydrogen partial pressure, low space velocity promote long run lengths

Isomerization yields controlled by chemical equilibrium
- Removing isoparaffins from feedstock can shift the reactor equilibrium & increase the final product octane

Temperature primary process control variable
- Higher temperatures increase processing severity (including hydrocracking)

Other process variables
- Higher pressures increase catalyst life but increases undesirable hydrocracking reactions
- Increased hydrogen partial pressure promotes hydrocracking but prolongs catalyst life
- Space velocity balanced against capital cost, temperature, run length & yields
Process Improvements

Removing isopentane from feed & bypass reactor

Use molecular sieves to remove & recycle normal-paraffins

- Separation carried out entirely in vapor phase — no reflux utilities but cyclic operation

Side draw of n-hexane, 2-methylpentane, 3-methylpentane & recycle

- Octane approaching 92 RON
- Suitable for blending into premium at no octane penalty

Isomerization Options

UOP’s Par-Isom process

Nonchlorided-alumina catalyst – regenerable & tolerant to sulfur & water

Typical product octanes 81 – 87 depending on flow configuration & feedstock qualities

Typically 97 wt% yield of fresh feed

GTC Technology’s Isomalk-2 process

Optimized for high conversion rate with close approach to thermal equilibrium

Produce up to 93 RON with full recycle

Operates 120°C – 180°C (250°F – 350°F)

Over 98% mass yield

Alkylation & Polymerization

Processes to make gasoline components from materials that are too light to otherwise be in gasoline

Alkylation

- Form a longer chain highly branched isoparaffin by reacting an alkyl group (almost exclusively isobutane) with a light olefin (predominately butylene)
- Produces high-octane gasoline

Polymerization

- Formation of very short chains
- Product is nearly all olefinic — high research octane but moderate motor octane number
U.S. Refinery Implementation

EIA, Jan. 1, 2016 database, published June 2016

Characteristics of Petroleum Products

Alkylation: combine small molecules for gasoline with good properties
Olefin Alkylation & Polymerization

1920s & 1930s other methods used to improve gasoline octane
- Tetra Ethyl Lead in Straight Run Gasoline
- Thermal reforming of naphtha
- Thermal polymerization of olefinic light ends to hexenes, heptenes, & octenes

In late 1930s & early 1940s, alkylation of olefins was developed to improve the octane of aviation gasoline
- Vladimir Ipatieff had discovered aluminum chloride catalysis in 1932

FCC significantly increased the production of light ends
- High concentration of the C3, C4, & C5 isomers, both olefinic & paraffinic
- Led to development of both catalytic polymerization & alkylation

Following end of the Korean conflict (1953) refiners investigated use of their catalytic polymerization and alkylation capacity for production of higher-octane motor fuels
- Chicken & egg — increasing octane production capacity & higher performance engines in automobiles led to the octane race in mid 1950s

Both polymerization & alkylation were adapted — alkylation became the dominant process

By the 1960s, polymerization units were being phased out & new plants utilized alkylation technology
Sulfuric Acid vs. HF Alkylation

Sulfuric Acid Alkylation

Developed by consortium of major refiners & contractors

- Anglo-Iranian Oil, Humble Oil & Refining, Shell Development, Standard Oil Development, & the Texas Company
- First unit at Humble Baytown Refinery, 1938
- Many alkylation plants were built at the same time as the catalytic cracking units
- Operated during World War II for aviation gasoline production

Sulfuric acid alkylation required access to acid regeneration on a large scale

- Most located on deep water for barge transport of spent acid to regeneration at acid plants & return of fresh acid
- Economic handicap for inland Midwestern refineries

HF Acid Alkylation

Separately developed by Phillips Petroleum & UOP

- HF could be readily regenerated in alkylation plant facilities
- No need to transport catalyst in large quantities for regeneration
Feedstocks & Products

Olefinic stream from the catalytic cracker
- Butylene preferred olefin – produces highest octane number & yields
- Isobutane & isopentane can be reacted with the olefin
  - Isopentane not usually used since it is a good gasoline blend stock

High octane number & low vapor pressure

Catalytic cracker feed contains significant sulfur
- Treating unit often precedes alkylation unit

Alkylate desirable component for high performance automotive fuels
- Very high octane index (R+M)/2 of 95
- Low vapor pressure
  - Vapor pressure is adjusted for final boiling point
  - IBP adjusted for addition of normal butane
- Low sulfur levels
- Essentially no olefins, benzene or aromatics
Feedstock Considerations

Olefin Feed

Butylene preferred
- Produces the highest isoctane levels
- Resulting Research Octane Numbers of 93-95 (with isobutane)
- RON and MON are about equal for alkylation
- Amounts of butylene consumed per alkylate produced is the lowest
- Side reactions are limited

Propylene worse
- Octane numbers are low (89-92 RON)
- Propylene & acid consumption are high

Pentene results are mixed
- Side reactions frequent

Isoparaffin Feed

Excess isobutane required — typical volume ratio of isobutane:olefin in the feed is 6-10
- Limited isobutane solubility in acid phase
- Olefins need to be surrounded by isobutane exposed to acid — if not, olefins will polymerize instead of alkylate

Newer plants have multi-injection & vigorous mixing systems
- Effect of isobutane is expressed in terms of concentration in the reaction zone
- Isobutane:olefin ratios maintained at 10,000:1
C4 Isomerization

UOP’s Butamer™ process is a high-efficiency, cost effective means to meet isobutane demands by isomerizing nC₄ to iC₄

Equilibrium limited
- Low temperature favors iC₄
- High-activity chlorided-alumina catalysts used

High selectivity to iC₄ by separating & recycling nC₄ to extinction
- Once-through lower capital cost

![Diagram of C4 Isomerization Process]
Process Chemistry Examples

Isobutylene & isobutane form 2,2,4-trimethylpentane (isooctane)

\[
\begin{align*}
\text{Isobutylene} & \quad \text{Isobutane} \\
\text{Propylene} & \quad \text{Isobutane}
\end{align*}
\]

Propylene & isobutane form 2,2-dimethylpentane as primary product with 2,3 & 2,4-dimethylpentane as secondary products

</tbody>
</table>
Alkylation Process Chemistry

Acid catalyzed alkylation combines isoparaffins & olefins to form alkylate, highly branched alkanes
- Usually only isobutane is used
- Isopentane can be a good gasoline blend stock for winter gasoline

Friedel-Crafts reaction — Lewis acid (HF or H2SO4) promotes carbonium ion on a tertiary isoparaffin that rapidly reacts with any double bond it encounters (propylene, butylenes, or pentylenes)

The reaction carried out in the liquid phase with an acid/reactant emulsion maintained at moderate temperatures

Propylene, butylene, & pentenes used — butylene preferred
- High octane isooctane alkylate produced
- Lower reactant consumption

Alkylation reactions have complex mechanisms & may produce many different varieties
Operating Variables & Their Effects

Capacity expressed in terms of alkylate product, not feed capacity

Most important variables

- Type of olefin
  - Propylene, butylene, or pentene
- Isobutane concentration – isobutane:olefin ratio
- Olefin injection & mixing
- Reaction temperature
- Catalyst type & strength

Critical measures for success

- Alkylate octane number
- Volume olefin & isobutane consumed per volume alkylate produced
  - Degree of undesirable side reactions
- Acid consumption
Isobutane/Olefin Injection & Mixing

More important in sulfuric acid systems
- Acid viscosity at operating temperatures

Provide optimal reaction conditions for the very fast reaction
- Inject olefin feedstock in incremental fashion to increase isobutane/olefin ratios
- Newer plants designed for multi-injection locations into an agitated emulsion to disperse olefin as rapidly as possible

Systems with single point injection can easily have an overload of olefin in the emulsion
- Leads to lower quality & higher acid consumption from esterification reactions
## Process Considerations

HF Alkylation System

Differences to sulfuric acid systems

- Feed driers essential to minimize catalyst consumption
  - Water forms an azeotrope with HF leading to acid loss
- HF stripper required on depropanizer overhead to clean up propane for LPG
- HF regenerator operating on a slip stream from acid settler
  - Many acid soluble organic compounds decompose but some must be rejected as acid soluble oil
- Spent acid requires special neutralization
  - Convert HF to calcium fluoride & burnable waste
  - Overall acid loss should be less than one pound per barrel of acid produced

Elaborate HF venting, neutralization & recovery system

- Considered by the public to be a threat in terms of large releases of HF
- New designs minimize the inventory of HF in the unit far below earlier designs
  - Risk is minimized, not eliminated

Supplemental Slides
Reformer Installed Cost

Includes

- ISBL facilities to produce 102 RON reformate from sulfur-free HSR naphtha
- Product debutanizer
- All necessary controllers & instrumentation
- All ISBL facilities
- Heat exchange to accept feed & release products at ambient temperature

Excludes

- Cooling water, steam & power supply
- Feed & product storage
- Initial catalyst charge
- Royalty
- Feed fractionation or desulfurization
