Biologically rich, laminated, photosynthetic microbial mats flourish on the floors of evaporating ponds at the Exportadora de Sal saltworks in Guerrero Negro, Mexico. This industrial operation pumps seawater out of the Laguna Ojo de Liebre, on the west coast of Baja California; the water is then gravity fed through ~185 km² of evaporative basins of increasing salinity. Microbial mats, 6 to 8 cm thick with a tofu-like consistency, have developed on the bottom of these ~1-m-deep ponds. The mats at Guerrero Negro have received considerable attention with regard to biogeochemistry and microbiology (1, 10, 13, 17). Photosynthetic microorganisms dominate the top few millimeters of the mat complex and produce oxygen during the day (10). The mat is permanently severely anoxic in the deeper layers, and throughout the mat at night, with high sulfide levels from metabolic sulfate reduction (15). Recent, small subunit rRNA gene sequence surveys have identified in the mat a spectacular diversity of bacterial species (10). Although a few eukaryotic rRNA gene sequences were detected, they were rare, amounting to ~0.5% of the total rRNA genes detected using universal PCR primers.

Most eukaryotic phylogenetic diversity is microbial in nature. Yet, the environmental diversity and distribution of microbial eukaryotes remain poorly understood and difficult to observe with the classical methods of microscopy and culture. Recent culture-independent molecular studies have expanded the known extent of eukaryotic phylogenetic diversity, including unique microbes from environments considered “extreme,” such as anoxic deep sea trenches (19), the McMurdo Dry Valleys of Antarctica (7), the endolithic environments of Yellowstone (20), anoxic sediments (2, 6), and others (11, 16). In considering that the chemical and bacterial diversity of the Guerrero Negro mat might also indicate high eukaryotic diversity, we undertook to determine the eukaryotic complexity of mat samples. Analyses were conducted through sequence-based identification of microbial eukaryotes based on PCR amplification and sequence analysis of small subunit rRNA genes.

In brief (detailed methods can be found in the supplemental material online and as described previously in references 10 and 20), DNA was purified from 10 vertical sections of ~6-cm cores (the top 6 mm was in millimeter-sized sections; below that were four sections of 1 cm each) from the well-studied site Pond Four (near Pond Five) at the saltworks site and used as the template for eukaryote-specific PCR amplification of the small-subunit rRNA gene. PCR products were cloned, and >2,000 randomly selected clones were screened by restriction fragment length polymorphisms (RFLP). Approximately 300 representative RFLP types were sequenced, and the results were compared to database sequences. About 50% of the sequences were representative of eukaryotes (many archaea were detected). Overall, this survey of eukaryotic diversity in the Guerrero Negro mat is based on 890 RFLP-type clones. This is a relatively limited sampling, but it is sufficient, from a population statistical point of view, to gain some insight into the local eukaryotic diversity in the context of high bacterial diversity (10).

Phylogenetic analyses of the sequences were conducted to identify the resident eukaryotes. The overall census is summarized in Fig. 1, and the distribution of sequences is given in Table 1. In light of the high bacterial diversity, the eukaryotic diversity detected was surprisingly low, only ~15 species-level groups representing six eukaryotic kingdom-level phyla were identified. Diversity estimates were utilized and they predicted 16 eukaryotic “species” in this sample (see methods described in the supplemental material). All sequences, with the exception of one cluster, were closely related to those of organisms previously described or to environmental sequences previously encountered. The novel sequences that had no kingdom-level affiliation with known sequences we termed Guerrero Negro Eucaryal Group 1 (GNEGI1). GNEGI1 sequences are all closely related, ~99% identity in rRNA sequence, and possibly allelic. This indicates that the same or highly similar organisms occur...
throughout the mat. Phylogenetic analyses of these sequences indicate a deeply branching eucaryotic lineage that is not “fast clock” and has no specific affiliation with any other clusters within the eucaryotic domain. Attempts to visualize the corresponding organism by fluorescence in situ hybridization were unsuccessful due to the overwhelming autofluorescence observed in these mats.

The most abundant eucaryal sequences detected, approximately half, were those of nematodes. In order to resolve the relationships of the sequences, we conducted an all-nematode phylogenetic analysis, which was largely congruent with that of Meldal and colleagues (11; see Fig. S1 in the supplemental material). Figure 2 shows the local grouping of the Monhysteridae and Rhabdolaimidae families, with which the Guerrero Negro sequences are affiliated. The limited variation in both groups of sequences (Table 1) is potentially allelic and in any case indicates that only two kinds of nematodes dominate the eucaryotic diversity of the mat at the site sampled.

The unusual properties of these nematodes, including their anaerobic lifestyle, their resistance to sulfide poisoning, and their persistence in the hypersaline state, encouraged efforts to cultivate them. A representative of the Monhysteridae family, a Diplolaimelloides sp. (Fig. 2), was cultured on 1.5% agar containing 1% NaCl and spread lightly with an autoclaved emulsion of the mat (see materials and methods described in the supplemental material). Microscopic examination (see Fig. S2 in the supplemental material) showed a pharynx typical of bacterivorous, free-living nematodes, sexual dimorphism of the tails, and anterodorsal ocelli that are red pigmented with a small white spot at the anterior tip (3, 4, 9).

Other conspicuous sequences in the mat include those of an insect and a crustacean, both of which are closely related to the rRNA sequences of named organisms (Table 1). The sequences are found mainly in the upper portion of the mat and presumably represent grazers of the mat. The only conspicuous photosynthetic organism detected by sequence (99% identity), the stramenopile Nannochloropsis gaditana, was located mainly at mid-depth in the mat. Presuming that the organism represented by the sequence conducts oxygenic photosynthesis, this may indicate that oxygen production occurs more deeply in the mat than generally considered.

This survey of the mat eucaryotes clearly is not comprehen-

† The frequency of each eucaryotic species is shown both overall and in three chemically distinct layers of the mat. Also shown are the nearest relatives, found by BLAST, and the intragroup sequence divergence.

* n, number of clones analyzed.

† Unaffiliated, ≤87% sequence identity to any previously sequenced rRNA gene.

‡ Based on 16 clones with sequences from nucleotide positions 3253 to 7823.

§ Based on 22 clones with sequences from nucleotide positions 3259 to 7817.

‖ Based on 10 clones with sequences from nucleotide positions 3253 to 7823.

∥ N/A, not applicable. Only one clone was sequenced, so no divergence can be calculated.
sive; most of the sequences derive from a limited diversity of organisms, and sequences representative of some groups were detected only once (Table 1). Nonetheless, and with acknowledgment of the caveats of molecular technology (e.g., PCR bias, variability in rRNA gene dosage [14], etc.), based on our study of multiple environments (6, 10, 17, 20), we believe the frequency with which rRNA genes are detected probably is a rough measure of the corresponding biomass.

The eucaryotic diversity of the Guerrero Negro mat is surprisingly sparse considering the vast bacterial diversity in the same setting. What might account for this disparity in species richness of bacteria and eucaryotes? The answer may lie in the differences in intrinsic metabolic capabilities of bacteria and eucaryotes. Bacteria collectively exhibit broad metabolic capabilities and can occupy the many chemical niches that are generated during the physiological function of the mat community. In contrast, the metabolic versatility of eucaryotes seems more limited, basically fermentative in the absence of sulfide, fermentative, anaerobic conditions. In contrast, the metabolic versatility of eucaryotes seems more limited, basically fermentative in the absence of bacterial symbionts, though capable of survival under high sulfide, fermentative, anaerobic conditions. The dominant org-

importance in the mat, the nematodes, evidently are bacteri-

vorous. The Monhysteridae nematodes are commonly found in marine sediments and are prevalent at the oxic-anoxic boundary (18). Although such organisms comprise only a small fraction of the total Guerrero Negro mat biomass, they are conspicuous and possibly play an important role in the community, for instance by imparting churning action and microbial/chemical transport within the mat (8). The diverse organisms detected provide good subjects for study of the ways in which eucaryotes adapt to environmental stresses such as extreme anoxia and drastic die sulfide fluctuations.

Nucleotide sequence accession numbers. Eucaryotic sequences were submitted to GenBank with accession numbers EF659781 to EF659934.

We thank Brad Bebout, Moira Doty, David DesMarais, Tori Hoehler, Mary Hogan, and Kendra Turk at the NASA Ames Research Center for permitting and for assistance at the field site. We also thank the Exportadora de Sal for support and access to these mats within their industrial saltworks, to members of the Pace laboratory for review and discussion, and to Jason Sahl at CSM for scanning electron microscopic images of nematodes.

This research was supported by funds to N.R.P. from the Astrobiology Institute of NASA and by an Agouron postdoctoral fellowship to J.R.S.
